# Segment 5: Analyzing Observational Studies

Section 05: Inverse Probability Weighting

# Inverse Probability of Treatment Weighting

One way we've seen to "restructure" the data:

- 1. Estimate the propensity score
- 2. Weight the sample  $\rightarrow$  pseudopopulation to approximate the design of a randomized trial
  - Weights will depend on the estimated propensity score
  - ► Treatment assignment will be unconfounded in the pseudopopulation

There are many methods for estimating causal effects that rely on this type of *Inverse Probability of Treatment* (IPTW) weighting

#### **IPTW:** Basic Intuition

**Goal:** Weight the observed sample to create a pseudopopulation that is balanced with respect to covariates (i.e., as though "randomized")

- ▶ The less likely a unit is to have received treatment  $Z_i = z$ , the larger representation it should get in the pseudopopulation
- ▶ Up-weight "weirdos": units whose treatment assignment is very different from what would be suggested by the propensity score
  - ▶ Unit  $Z_i = 1$  and  $e_i(X_i) = 0.05$  gets a weight of  $\frac{1}{0.05} = 20$ ▶ Unit with  $Z_i = 1$  and  $e_i(X_i) = 0.9$  gets weight of  $\frac{1}{0.9} = 1.11$
- Weights adjust for confounding by creating a pseudiopopulation where all individuals have the same probability of receiving Z=1 and Z=0
- Rooted in ideas of survey sampling

## **Example: IPTW Intuition**

(adapted from Hernan and Robins textbook)

1       0       0       0         2       0       0       1         3       0       0       0         4       0       0       0         5       0       1       0         6       0       1       0         7       0       1       0         8       0       1       1         9       1       0       1         10       1       0       1         11       1       0       0         12       1       1       1         13       1       1       1         14       1       1       1         15       1       1       1         16       1       1       1         17       1       1       1         18       1       1       0         20       1       1       0		$X_i$	$Z_i$	$Y_i^{obs}$

- ▶ What is  $Pr(Y_i(0) = 1)$ : Prob of complication if everyone had received control?
- ▶ If all 20 patients had received  $Z_i = 0$ 
  - ▶ 2 (not 1) would have complications among the  $X_i = 0$  patients
  - ▶ 8 (not 2) would have complications among the  $X_i = 1$  patients
- $ightharpoonup \Rightarrow Pr(Y_i(0) = 1) = \frac{10}{20} = 0.5$
- ▶ Analogously,  $Pr(Y_i(1)) = 1) = 0.5$

(Why can we assume that the rate of complication would have been the same in each level of  $X_i$ ?)

# Inverse Probability Weighting: Intuition

- Think about two hypothetical scenarios where all are treated or untreated
- ► **Key Idea:** Combine those two hypothetical situations to create a hypothetical population in which every unit appears as *both* treated and untreated
  - ► A pseudopopulation larger than the observed data
- With conditionally unconfounded treatment assignment, the pseuodopopulation will have unconditionally unconfounded assignment
  - ► I.e., the covariate distribution will be the same in the treated and control group
- ➤ ⇒ The treated/control contrast in the pseudopopluation represents a causal effect (without further adjustment in the pseudopopulation)

- Consider the 4 units with  $Z_i = 0$  and  $X_i = 0$ 
  - Used to create 8 units in the pseudopopulation
  - ▶ Each receives weight,  $w_i = 2 = \frac{1}{0.5}$
  - $Pr(Z_i = 0|X_i = 0) = 0.5$
- Consider the 9 units with  $Z_i = 1$  and  $X_i = 1$ 
  - Used to create 12 members of the pseudopopulation
  - Each receives weight,  $w_i = 1.33 = \frac{1}{0.75}$
  - $Pr(Z_i = 1|X_i = 1) = 0.75$

# Inverse Probability Weighting

In general, for unit i with  $X_i = x$  and  $Z_i = z$ 

$$w_i = \frac{1}{Pr(Z_i = z | X_i = x)}$$

More generally,

$$w_i = \frac{1}{f(Z_i|X_i)} = \frac{Z_i}{e_i(X_i)} + \frac{1 - Z_i}{1 - e_i(X_i)}$$

Inverse of probability of receiving the treatment actually received.

For estimating causal effects:

$$E[Y(z)] = E\left[\frac{I(Z=z)Y^{obs}}{f(Z|X)}\right]$$

# IP Weights Based on Propensity Scores

- lacktriangle In simple cases, could estimate Pr(Z|X) nonparametrically
  - lacktriangle Ensure exact balance on X in the pseudopopulation
- We have already discussed why this may not be feasible and motivated the propensity score  $e(X_i)$  (and its estimate) as a quantity that can
- ► The idea for IPW with the estimated propensity score extends in a straightforward way
  - Where  $\hat{e}_i(X_i)$  comes from a parametric model
  - ► Should create balance on *propensity score* in pseudopopulation
  - ► Should still check balance on individual covariates in the pseudopopulation

$$w_i = \frac{Z_i}{\hat{e}(X_i)} + \frac{(1 - Z_i)}{(1 - \hat{e}(X_i))}$$

#### **IPTW Intuition**

#### Based on propensity scores

- $Z_i = 1, \hat{e}(X_i) = 0.05$ 
  - $\Rightarrow$  Unit i has  $X_i$  that look different from other Z=1 units
  - $\Rightarrow$  Units with this  $X_i$  are underrepresented in the Z=1 group
  - $\Rightarrow$  Upweight them by  $\frac{1}{0.05}$
  - ⇒ Represent 20 observations in the pseudopopulation
- $Z_i = 1, \hat{e}(X_i) = 0.90$ 
  - $\Rightarrow$  Unit i has  $X_i$  that look similar to other Z=1 units
  - $\Rightarrow$  Units with this  $X_i$  are common in the Z=1 group
  - $\Rightarrow$  Upweight them by  $\frac{1}{0.90}$
  - $\Rightarrow$  Represent 1.11 observations in the pseudopopulation

# Estimating the ATE with IPW

Difference in the mean of the weighted outcomes is an unbiased estimate of the ATE:

$$\hat{\tau}_{ipw,1} = \frac{1}{N} \left( \sum_{i=1}^{N} \frac{Y_i Z_i}{e(X_i)} - \sum_{i=1}^{N} \frac{Y_i (1 - Z_i)}{1 - e(X_i)} \right)$$

$$= \frac{1}{N} \sum_{i=1}^{N} \left( Y_i Z_i w_1(X_i) - Y_i (1 - Z_i) w_0(X_i) \right)$$

where  $w_1(X_i)=\frac{1}{e(X_i)}$  and  $w_0(X_i)=\frac{1}{1-e(X_i)}$  are weights for the treated, untreated, respectively

In practice, replace  $e(X_i)$  with  $\hat{e}(X_i)$ , which actually improves efficiency

In practice, frequently accomplished with the library(survey) package in R

#### **IPW Notes**

#### Advantages

- Elegant theoretical foundation
- Improved efficiency (relative to matching or coarser stratification)
- Extension to more complex settings (e.g., time-varying treatments)
- Can be thought of as a continuation of stratification as the # of strata goes up and size of strata goes down

#### Disadvantages

- More sensitive to propensity score model specification
  - ► E.g., vs. stratification, which "shrinks" or "smooths" weights to the average within the stratum
- $\hat{e}(X_i)$  near 0 or 1 o very extreme weights
  - $e(X_i) \to 1: w_1(X_i) \to$
- Erratic finite sample performance
- Results can be dominated by a few observations
